

Regge residues from DGLAP evolution

G. Soyez*

Inst. de Physique, Bât. B5, Université de Liège, Sart-Tilman, B4000 Liège, Belgium

We show that combining forward and backward evolution allows to extract the residues of the triple-pole pomeron and of the other singularities for $10 \text{ GeV}^2 \leq Q^2 \leq 1000 \text{ GeV}^2$. In this approach, the essential singularity generated by the DGLAP evolution is considered as a numerical approximation to a triple-pole pomeron. Using an analytical expression for the form factors, we reproduce the experimental data with a χ^2/dof of 1.02. This proves the compatibility between Regge theory and DGLAP evolution. The method used here enables us to evaluate the uncertainties on the gluon distribution which prove to be large at small x and small Q^2 .

I. INTRODUCTION

Deep Inelastic Scattering (DIS) is a very important tool to study the fundamental behaviour of strong interactions. The numerous available data, especially the last ones from HERA, which have very small error bars, allow for a direct test of theoretical models.

The work presented here puts together two major theoretical approaches: perturbative QCD (pQCD), through the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) evolution and analytical S -matrix theory, through Regge theory, on the other. Models using one or the other are numerous. On the one hand, there are a lot of well-known DGLAP fits to experimental data [1, 2, 3, 4, 5] which reproduce very well the experimental data. However, in the usual parton distribution sets, each initial parton distribution presents its own singularities. As an example, in the MRST2001 parametrization [1], we have

$$xq(x, Q_0^2) = A(1 + B\sqrt{x} + Cx)(1 - x)^{\eta_q} x^{\varepsilon_q},$$

with $\varepsilon_{\text{sea}} = -0.26$, $\varepsilon_g = -0.33$. Such a behaviour is not consistent with Regge theory. On the other hand, Regge theory establishes strong constraints on the large s (small x) behaviour of total cross sections, and Regge-compatible fits to experimental data are also numerous [6, 7, 8, 9, 10]. In those fits, the residues of the Regge poles are unknown functions of Q^2 , and one can only predict F_2 while quarks and gluon distribution functions remain out of reach.

In a previous paper [11], we have shown that one can use a triple-pole pomeron to parametrize the initial parton distribution functions and let them evolve according to the DGLAP equation. In this approach, both quarks and gluons have the same singularity structure. Our model is therefore compatible both with Regge theory and with pQCD. In addition, we predict a gluon distribution of the same order of magnitude as the one obtained in the usual DGLAP fits.

We now want to explore whether it is possible to avoid the essential singularity coming from DGLAP evolution and extend the Regge fit to large Q^2 values. In other words, can we use the DGLAP evolution equations to find the Q^2 dependence of the Regge form factors? To answer that question, the main obstacle lies in the fact that the DGLAP evolution generates an essential singularity which seems to be incompatible with the Regge ones. To solve that problem, we need to remember that the DGLAP evolution is only an approximation and that only a full resummation of the perturbative series - including all order corrections to DGLAP, small- x and higher-twist effects - should give the correct analytical behaviour. From the large number of DGLAP fits, one expects corrections to be small and DGLAP to be a good approximation. We will therefore choose a Regge compatible singularity structure and an initial scale Q_0^2 for DGLAP evolution, and then adjust the initial distribution in order to reproduce the experimental data as well as possible. In this way, we obtain the residues at scale Q_0^2 and, repeating this procedure for different values of Q_0^2 we get the Regge form factors for the full range of the initial scale. In this method, it is important to note that we keep a common singularity structure, namely a triple-pole pomeron and an f, a_2 -reggeon, in all parton distributions.

The structure of the paper is as follow: in section 2, we introduce the basics of DGLAP evolution and Regge theory, we emphasise the tools needed in the rest of the paper and we summarise previous work. In section 3, we give the form of the initial distribution that we will use as initial condition for DGLAP evolution and that is obtained from Regge theory. Section 4 tells how we use DGLAP evolution to obtain the form factors and section 5 gives the results of the fit. We conclude in section 6.

II. PERTURBATIVE QCD AND REGGE THEORY

A. Perturbative QCD

In pQCD, the high- Q^2 behaviour of DIS is given by the DGLAP evolution equations [12]. These equations introduce the *parton distribution functions* $q_i(x, Q^2)$, $\bar{q}_i(x, Q^2)$ and $g(x, Q^2)$, which can be interpreted as the probability of finding, in the proton, respectively a quark, an anti-quark or a gluon with virtuality less than Q^2 and with longitudinal momentum fraction x . When $Q^2 \rightarrow \infty$, the Q^2 evolution of these densities (at fixed x) are given by the DGLAP equations

$$Q^2 \partial_{Q^2} \begin{pmatrix} q_i(x, Q^2) \\ \bar{q}_i(x, Q^2) \\ g(x, Q^2) \end{pmatrix} = \frac{\alpha_s}{2\pi} \int_x^1 \frac{d\xi}{\xi} \begin{pmatrix} P_{q_i q_j} & \cdot & P_{q_i g} \\ \cdot & P_{q_i q_j} & P_{q_i g} \\ P_{gq} & P_{gq} & P_{gg} \end{pmatrix} \bigg|_{\frac{x}{\xi}} \begin{pmatrix} q_j(\xi, Q^2) \\ \bar{q}_j(\xi, Q^2) \\ g(\xi, Q^2) \end{pmatrix}. \quad (1)$$

At leading order, P_{xy} does not depend on Q^2 . The connection to F_2 is given by

$$F_2(x, Q^2) = x \sum_i e_{q_i}^2 [q_i(x, Q^2) + \bar{q}_i(x, Q^2)], \quad (2)$$

where the sum runs over all quark flavours.

The usual way to use this equation is to choose a set of initial distributions $q_i(x, Q_0^2, \vec{a})$ to compute $q_i(x, Q^2, \vec{a})$ using (1) and to adjust the parameters $\vec{a}$ in order to reproduce the experimental data. This approach have already been successfully applied many times [1, 2, 3, 4, 5] and is often considered a very good test of pQCD. Nevertheless, these studies do not care about the singularity structure of the initial distributions, ending up with results that disagree with Regge theory, and presumably with QCD.

B. Regge theory

Beside the predictions of pQCD, we can study DIS through its analytical properties. In Regge theory [13, 14], we consider amplitudes $\mathcal{A}(j, t)$ in the complex angular momentum space by performing a Sommerfeld-Watson transform. In that formalism, the large- s dependence of amplitudes is determined by their singularity structure in j -plane. The singularities are functions of t only and this technique can be applied to the domain $\cos(\theta_t) \gg 1$, where θ_t is the deviation angle in the center-of-mass frame for the t -channel amplitudes and where amplitudes are analytically continued to any $\cos(\theta_t)$ value. For example, we can fit the DIS data or the photon structure function at large $p.q \equiv \nu$ (small x), and the total cross sections at large s .

The models based on Regge theory [7, 8, 9, 15] use a pomeron term, reproducing the rise of the structure

function (resp. cross sections) at small x (resp. large s), and reggeon contributions coming from the exchange of meson trajectories (a and f).

We shall consider here the following parametrization for the pomeron contribution to F_2 or to σ_{tot} :

$$a(Q^2) \ln^2 [\nu/\nu_0(Q^2)] + c(Q^2), \quad (3)$$

corresponding to a triple pole in the complex j -plane [6]

$$\frac{a}{(j-1)^3} - \frac{2a \ln(\nu_0)}{(j-1)^2} + \frac{a \ln^2(\nu_0) + c}{j-1}.$$

This seems to be the preferred phenomenological choice at $Q^2 = 0$ [10]. Note that the upper expression, given in terms of ν and Q^2 , can be rewritten in terms of Q^2 and $x = Q^2/(2\nu)$. So, the x behaviour of the structure functions is constrained by Regge theory.

However, this approach has two problems:

1. it only predicts F_2 , while a full set of parton distribution functions is needed,
2. it does not give any information about the Q^2 dependence of the residues.

III. MIXING DGLAP EVOLUTION WITH REGGE THEORY

From a previous study [11], we have learned that the small- x behaviour of the parton distributions can be described by a triple-pole pomeron model at the initial scale Q_0^2 and then evolved using the DGLAP equation. We can summarise these results as follows:

- *It is possible to have the same singularity structure for quarks and gluons, in agreement with Regge theory.*
- One can use a triple-pole pomeron to parametrize the initial parton distributions. In particular, we predict a gluon distribution compatible with usual ones.
- The DGLAP evolution generates an essential singularity at $j = 1$. We expect that this singularity is purely of perturbative origin and that a full resummation of QCD should lead to a Regge-compatible singularity structure.
- The F_2 residues were fixed to reproduce results from the soft QCD fit [6] which goes down to $Q^2 = 0$.

We show here that we can use this trick to obtain form factors which are compatible with DGLAP evolution. We present in this section the model used to extract these residues as a function of Q^2 . In summary, always considering that DGLAP evolution does not lead to a relevant singularity structure but only to an approximation of the

parton distributions, we consider that the initial distribution fitted by starting the evolution at the scale Q_0^2 gives the residues at Q_0^2 . We just need to repeat this by varying Q_0^2 to get the residues over the whole Q^2 range. Note that since we want to *predict* the F_2 residues, we do not constrain F_2 with a soft QCD fit as it was done in [11]. However, it is known that the triple-pole pomeron model can be used to reproduce soft processes. Therefore, one knows that the residues found here can be extended down to $Q^2 = 0$. Since we only want to study the domain where both DGLAP and Regge theory are expected to apply, we won't go into such an extension.

Regge theory is expected to be valid for $\cos(\theta_t) \gg 1$. In the case of DIS, $\cos(\theta_t) = \frac{\sqrt{Q^2}}{x m_p}$, where m_p is the mass of the proton. The Regge region is thus

$$\frac{\sqrt{Q^2}}{x m_p} \geq K, \quad (4)$$

with K a fixed number. We clearly see that the domain does not extend up to $x = 1$. However, in the DGLAP evolution equations (1) the small- x domain is coupled to large- x values and therefore we need a parametrization for the parton distribution functions at large x . The ideal case is certainly the introduction of powers of $(1-x)$, or of any polynomial vanishing at $x = 1$, in our initial distributions. This should take into account daughter trajectories in Regge theory and ensure that parton distributions go to 0 as $x \rightarrow 1$. Unfortunately, this has two drawbacks:

1. it introduces a lot of additional parameters which are not directly related to the small- x Regge behaviour,
2. a precise description of the parton distributions at large x requires more than simply fitting F_2^p and splitting it into flavor singlet component, coupled to the gluons, and one additional non-singlet distribution. We need to introduce valence quark distributions and sea quark distributions. Fitting many kinds of experiments like F_2^p , F_2^n , F_2^d , $F_2^{\nu N}$ and $x F_3^{\nu N}$ allows to constraint all these distributions separately. Again, introducing more parton distributions requires more parameters. Moreover, most of the experimental points except those from F_2^p , lies outside the region of interest (4).

In order to keep the parameters of our model as closely linked as possible to the Regge domain of the evolution, we will use an external distribution for the large- x parton distributions. As done in [11], we will use GRV98 [2] at large x . We have already argued that the results do not depend much on that choice and that their leading singularity structure is not affected by the parametrization at large x . Practically, we shall use the GRV parametrization for $x \geq x_{\text{GRV}}$ and our analytical form at small x .

FIG. 1: Number of points involved in the forward evolution

IV. INITIAL DISTRIBUTIONS

In order to reproduce F_2^p , we do not need the full set $\{q_i, \bar{q}_i, g\}$ of parton distributions. One can quickly check that the minimal set of distributions required is

$$T = x [(u^+ + c^+ + t^+) - (d^+ + s^+ + b^+)], \quad (5)$$

$$\Sigma = x [(u^+ + c^+ + t^+) + (d^+ + s^+ + b^+)], \quad (6)$$

$$G = xg, \quad (7)$$

where $q^+ = q + \bar{q}$ for $q = u, d, s, c, t, b$. The T distribution is a flavor non-singlet distribution, its Q^2 evolution is decoupled from any other distribution and is given by a DGLAP equation with $xP_{qq}(x)$ as splitting function. The sea quark distribution Σ is flavor singlet and evolves coupled to the gluon distribution using the full splitting matrix.

Using these distributions, the proton structure function becomes

$$F_2 = \frac{5\Sigma + 3T}{18}.$$

In order to perform a DGLAP evolution, we must find an analytical expression for the x dependence of these distributions at a scale Q_0^2 , where evolution will start. Since we want to describe F_2 as a triple-pole pomeron and a reggeon (f, a_2 -trajectories), and since adding new singularities in the parton distributions disagrees with Regge theory, the T , Σ and G distributions will be described by:

$$T(x, Q_0^2) = a_T \log^2(1/x) + b_T \log(1/x) + c_T + d_T x^\eta,$$

$$\Sigma(x, Q_0^2) = a_\Sigma \log^2(1/x) + b_\Sigma \log(1/x) + c_\Sigma + d_\Sigma x^\eta,$$

$$G(x, Q_0^2) = a_G \log^2(1/x) + b_G \log(1/x) + c_G + d_G x^\eta.$$

Out of the 12 parameters in the above expressions, some may be removed. First of all, we expect that the pomeron, having vacuum quantum numbers, does not distinguish between quark flavours. This means that it

is decoupled from the T distribution and that we may set $a_T = b_T = c_T = 0$. Then, since the reggeon is mainly constituted of quarks, we shall neglect its contribution to the gluon distribution and set $d_G = 0$.

In addition, we ask our distributions to be continuous with GRV's at $x = x_{\text{GRV}}$. This is used to fix d_T , c_Σ and c_G .

Finally, we have seen that we obtain much better results if we multiply each distribution by some power of $(1-x)$. This new factor, effectively including daughter trajectories, is expected from Regge theory. As already pointed out, this factor is not directly connected to the small- x domain. One can see that its main effect is to reproduce an inflexion point present around $x \approx 0.01$ in the parton distributions. In order to minimise the number of parameters, we used only two different powers in all distributions. We thus end with the following functions

$$\begin{aligned} T(x, Q_0^2) &= d_T^* x^\eta (1-x)^{b_2}, \\ \Sigma(x, Q_0^2) &= a_\Sigma \log^2(1/x) + b_\Sigma \log(1/x) + c_\Sigma^* (1-x)^{b_1} \\ &\quad + d_\Sigma x^\eta (1-x)^{b_2} \\ G(x, Q_0^2) &= a_G \log^2(1/x) + b_G \log(1/x) + c_G^* (1-x)^{b_1}. \end{aligned}$$

The parameters with a superscript * are constrained by continuity with GRV parametrisation and 7 free parameters remain: a_Σ , b_Σ , d_Σ , a_G , b_G , b_1 and b_2 .

These parameters must depend on Q_0^2 and we will see in the next section how we can find their Q^2 dependence.

V. FITTING THE FORM FACTORS

It is well-known that DGLAP evolution generates an essential singularity at $j = 1$. From that point of view, finding the Q^2 dependence of the residues of a triple-pole pomeron may seem impossible. However, DGLAP evolution always involves a finite order calculation of the splitting functions and, moreover, it resums large Q^2 corrections while resumming large s (small x) contributions should be preferable for a comparison with Regge theory. Consequently, we argue that the singularity structure generated by DGLAP evolution is physically irrelevant and that only a full resummation of QCD should end up on a correct Regge behaviour.

One must note that if we consider a resummation *à la* BFKL, we have a stable square-root branchpoint instead of an essential singularity. Furthermore, even in this case we still need to unitarize the pomeron, which may lead to another singularity structure.

So, which singularity do we need to take? How can we use the DGLAP evolution to calculate residues in Regge theory? Our point of view is that, although it doesn't provide a correct Regge behaviour, DGLAP evolution can still be considered as a good numerical approximation. In such a case, the only place where Regge theory can be used is for the initial distribution. We end up

FIG. 2: Form factors as functions of Q_0^2

with a Regge-compatible distribution at the initial scale Q_0^2 and a DGLAP approximation everywhere else.

As we shall see, obtaining the Regge residues from this technique is a quite straightforward.

A. Scheme 1

As initial condition for DGLAP evolution, we shall use the distributions obtained in section IV for $x \leq x_{\text{GRV}}$ and the GRV98 distribution for larger x values. The parameters are considered as functions of Q^2 and they can be found as follows:

1. choose an initial scale Q_0^2 ,
2. choose a value for the parameters in the initial distribution,
3. compute the parton distributions at larger Q^2 using DGLAP evolution equations,
4. repeat 2 and 3 until you find the best values of the parameters reproducing the experimental F_2 data for $Q^2 > Q_0^2$ and $x \leq x_{\text{GRV}}$.
5. This gives the residues at the scale Q_0^2 and we repeat steps 1 to 4 in order to obtain the residues at all Q^2 values.

This technique works quite well but has one drawback: calculation of the residues at the scale Q_0^2 relies on the experimental points satisfying

$$Q_0^2 \leq Q^2 \leq Q_{\text{max}}^2.$$

Unfortunately, this domain depends on the initial scale and as we can see on Fig. 1 the number of points used for the fit decrease quite fast when Q_0^2 rises.

B. Scheme 2

There is a way to keep the same set of points in each fits: adding backward evolution. The previous scheme thus becomes

1. choose an initial scale Q_0^2 ,
2. choose a value for the parameters in the initial distribution,
3. compute the parton distributions for $Q_0^2 \leq Q^2 \leq Q_{\text{max}}^2$ using forward DGLAP evolution and for $Q_{\text{min}}^2 \leq Q^2 \leq Q_0^2$ using backward DGLAP evolution,
4. repeat 2 and 3 until you find the value of the parameters reproducing the F_2 data for $Q^2 > Q_{\text{min}}^2$ and $x \leq x_{\text{GRV}}$.
5. This gives the residues at the scale Q_0^2 and we repeat steps 1 to 4 in order to obtain the residues at all Q^2 values.

This way, we take into account the experimental points with $Q_{\text{min}}^2 \leq Q^2 \leq Q_{\text{max}}^2$ whatever the value of Q_0^2 is.

TABLE I: Experimental points in the domain (8) and results of the analytical triple-pole fit

VI. RESULTS

We have chosen to use the second scheme with both forward and backward evolution. We have fitted the data in the region

$$\begin{cases} 10 \leq Q^2 \leq 1000 \text{ GeV}^2, \\ x \leq x_{\text{GRV}} = 0.15, \\ \cos(\theta_t) = \frac{\sqrt{Q^2}}{xm_p} \geq \frac{49 \text{ GeV}^2}{2m_p^2}. \end{cases} \quad (8)$$

This method ensures that Q^2 is large enough to apply DGLAP evolution, that $\cos(\theta_t)$ is large enough to use Regge theory and that the large- x domain is excluded from the fit. The limit on $\cos(\theta_t)$ has been taken from the pure Regge fit of [6]. In this region, the experimental points are as shown in Table I.

A. Form factors

When we apply the method explained in section VB using the parametric distributions obtained in section IV, we obtain the form factors presented in Fig. 2 and calculated from 10 to 1000 GeV^2 . The χ^2 per data point obtained for each fit, shown in Fig. 3, is of order 1 and the form factors appear to be smooth functions of Q_0^2 .

Finally, when choosing x_{GRV} , we do not want to take the high- x experimental points for reasons explained previously, but we want to set x_{GRV} as high as possible

to maximize the number of experimental point as possible, particularly in the large Q^2 domain where DGLAP evolution is expected to work better. We found that $x_{\text{GRV}} = 0.15$ was a good compromise between those constraints.

B. Parton Distributions

Once we have fitted the form factors, it is interesting to see if the distributions we obtain at a scale Q_0^2 are the same if we start evolution at Q_0^2 or if we start at Q_1^2 and evolve until Q_0^2 . As we see in Fig. 4, for the sea-quark distribution, the difference is very small. This shows clearly that the DGLAP essential singularity can be considered as a numerical approximation to a triple-pole singularity, at least for quarks.

For the gluon case, presented in Fig. 5, things are different. One can see that backward evolution tends to produce lower gluon distribution at small x . These can even become negative if we evolve to lower Q^2 values. However, the structure function only depends on the quark distributions which is stable as shown in Fig. 4. Thus, from the phenomenological point of view, all these distributions provide a correct description of the data and are perfectly acceptable. The differences in the gluon distribution obtained for different values of Q_0^2 must therefore be considered as uncertainties on the gluon distribution. One clearly sees from Fig. 5 that even at $Q^2 = 10 \text{ GeV}^2$, the uncertainties are very large. These large errors on the gluon distribution at small x and small Q^2 can be of prime importance in the study of LHC physics.

C. Analytical form factors

As a final step, we have tried to find analytical expressions for the form factors produced by the fit. Actually, it is much easier to work with analytical expressions reproducing results of Fig. 2 than to refit everything for each Q_0^2 values. In the Q^2 -range studied here, we have found that the following expressions, plotted in Fig. 2, reproduce very well the form factors extracted from the DGLAP fit.

$$\begin{aligned}
 a_\Sigma &= 0.29 \left(\frac{Q^2}{Q^2 + 123.3} \right)^{0.65} \\
 b_\Sigma &= \left[0.0048 \ln^2 \left(\frac{Q^2}{9.666} \right) - 0.114 \right] \ln^2 \left(\frac{Q^2}{9.666} \right) - 0.077 \\
 c_\Sigma &= \left[0.218 - 0.02 \ln^2 \left(\frac{Q^2}{13.1} \right) \right] \ln^2 \left(\frac{Q^2}{13.1} \right) - 0.13 \\
 d_\Sigma &= 2.66 \ln^2 \left(2.83 + \frac{Q^2}{199.13} \right) \\
 d_T &= 0.82 \left(\frac{Q^2}{Q^2 + 301.8} \right)^{0.105} \\
 b_1 &= 2.367 + \ln^{3.38} \left(1.0 + \frac{25.63}{Q^2} \right) \\
 b_2 &= 4.78 \left(\frac{Q^2}{Q^2 + 181.8} \right)^{0.21}
 \end{aligned}$$

Using these analytical expressions, one can compare their predictions with the experimental data. We obtain a χ^2 of 1.02 per data point, in a very good agreement with experimental measurements. The results are presented in Table I and in Figs. 6 and 7.

In the above equations, we only wanted to find some analytical expression reproducing the form factors extracted numerically from the DGLAP fits. We have not taken care of their analytical properties in Q^2 . To obtain better expressions, one should find an analytical equation for the form-factors Q^2 -evolution. Since we have seen that the evolved distributions, containing an essential singularity, are numerically close to the triple-pole distributions, one may hope that subleading corrections to the DGLAP equations will stabilize a triple-pole distribution.

D. F_2^c and F_L

Although only F_2^p is included in the fit, it is interesting to see if our predictions agree with the measurements of F_2^c [22, 24, 25] and F_L [20]. Actually, these quantities are directly sensitive to the gluon distribution and are therefore a good test of our predictions. The charm structure function is given by [26]

$$\begin{aligned}
 F_2^c(x, Q^2) &= 2e_c^2 \frac{\alpha_s(Q^2 + 4m_c^2)}{2\pi} \\
 &\quad \int_{ax}^1 d\xi g(\xi, Q^2 + 4m_c^2) f(x/\xi, Q^2),
 \end{aligned}$$

FIG. 4: Σ distribution at various Q^2 . Different curves correspond to different values of Q_0^2 .

FIG. 5: gluon distribution at various Q^2 . Different curves correspond to different values of Q_0^2 .

FIG. 6: F_2 fit using analytical approximation of the residues (low Q^2 values).

FIG. 7: F_2 fit using analytical approximation of the residues (high Q^2 values).

with

$$\begin{aligned}
 f(x, Q^2) &= v \left[(4 - \mu)x^2(1 - x) - \frac{x}{2} \right] \\
 &+ L \left[\frac{x}{2} - x^2(1 - x) + \mu x^2(1 - 3x) - \mu^2 z^3 \right], \\
 \mu &= \frac{2m_c^2}{Q^2}, \\
 v &= \sqrt{1 - \frac{2x\mu}{1-x}}, \\
 L &= \log \left(\frac{1+v}{1-v} \right) \\
 a &= 1 + 2\mu.
 \end{aligned}$$

We have adopted a value of 1.3 GeV for the charm quark mass and the predictions for F_2^c obtained from our model are presented in Fig. 8. We see that the data are quite well reproduced.

For the case of the longitudinal structure function, we are sensitive both to quarks and gluons:

$$F_L = \sum_{q=u,d,s,c} G_q + \frac{4\alpha_s(Q^2)}{3\pi} \int_x^1 \frac{d\xi}{\xi} \left(\frac{x}{\xi} \right)^2 F_2(\xi, Q^2),$$

where

$$\begin{aligned}
 G_q &= 2e_q^2 \frac{\alpha_s(Q^2 + 4m_q^2)}{\pi} \int_{ax}^1 d\xi \left(\frac{x}{\xi} \right)^2 g(\xi, Q^2 + 4m_q^2) \\
 &\quad \left[\left(1 - \frac{x}{\xi} \right) v - \frac{\mu x}{\xi} L \right]
 \end{aligned}$$

with $m_u = m_d = m_s = 0$ and $m_c = 1.3$ GeV. The results obtained from our parton distributions set are shown in Fig. 9 and show good agreement with the data.

VII. CONCLUSION

In summary, we have seen in this paper that DGLAP evolution can be used to extract the residues of a triple-pole pomeron model. We chose triple-pole distributions for both quarks and gluons at an initial scale Q_0^2 and we evolved them using DGLAP evolution. A comparison with the experimental data gives the residues of the triple-pole pomeron at the scale Q_0^2 . In order to keep the same data points when Q_0^2 varies, we evolved the initial distribution both forward and backward between $Q_{\min}^2$ and $Q_{\max}^2$. We have repeated that fit for various values of Q_0^2 resulting in smooth form factors for the triple-pole residues.

FIG. 8: Predictions for the charm structure function using our gluon distributions

FIG. 9: Predictions for the longitudinal structure function using our parton distributions

In this model, quarks and gluons have the same singularity structure, as suggested by Regge theory. The essential singularity generated by DGLAP evolution appears to be a good numerical approximation to a triple pole for the F_2 structure function. For the gluons, we found that there were quite large uncertainties in the gluon distribution at small x and small Q^2 . These uncertainties should certainly be taken into account in the LHC phenomenology.

Finally, we were able to find analytical expressions for our form factors. A comparison of these expressions with experimental data gives a χ^2 per point of 1.02, which proves the very good agreement between pQCD and Regge theory. We have also checked that our gluon distribution was acceptable by comparing our predictions for F_2^c and F_L with the H1 and ZEUS measurements.

Fitting the parton distributions up to $x = 1$ involves many complications, therefore we used the GRV98 parametrization for the large- x behaviour. As pointed out previously, this does not influence the small- x dis-

tributions much. Extension of this model up to $x = 1$ is left for future work. Since we know that Regge models can reproduce soft-processes measurements, it should also be very interesting to check that we can also extend the form factors found in this paper down to $Q^2 = 0$.

Finally, we used DGLAP evolution to *extract* the residues from the data. As we have seen, these are smooth functions of Q^2 and give numerical predictions close to the DGLAP essential singularity. It should therefore be of prime interest to find an equation which stabilizes the triple-pole singularity and keeps the correct large- Q^2 behaviour.

Acknowledgments

I would like to thanks J.-R. Cudell for useful discussions. This work is supported by the National Fund for Scientific Research (FNRS), Belgium.
